# ABSTRACT

There are several data based methods in the field of artificial intelligence which are nowadays frequently used for analyzing classification problems in the context of medical applications. As we show in this paper, the application of enhanced evolutionary computation techniques to classification problems has the potential to evolve classifiers of even higher quality than those trained by standard machine learning methods. On the basis of three medical benchmark classification problems, namely the Wisconsin and the Thyroid data sets taken from the UCI repository as well as the Melanoma data set prepared by members of the Department of Dermatology of the Medical University Vienna, we document that the enhanced genetic programming based approach presented here is able to produce better results than linear modeling methods, artificial neural networks, kNN classification and also standard genetic programming approaches.

#### 1. INTRODUCTION

Classification is understood as the act of placing an object into a set of categories, based on the object's properties. Objects are classified according to an (in most cases hierarchical) classification scheme also called taxonomy. Amongst many other possible applications, examples of taxonomic classification are biological classification (as for example the act of categorizing and grouping organisms into species), medical classification and security classification (where it is often necessary to classify objects or persons for deciding whether a problem might arise from the present situation or not).

A statistical classification algorithm is supposed to take feature representations of objects and map them to a special, predefined classification label. Such classification algorithms are designed to learn (i.e. to approximate the behavior of) a function which maps a vector of object features into one of several classes; this is done by analyzing a set of inputoutput examples ("training samples") of the function. The basic steps can be summarized as follows: After training the algorithm using a set of training samples, the algorithm should be able to classify a new, unknown object into one of the predefined classes by analyzing its measured features. Since statistical classification algorithms are supposed to "learn" such functions, we are dealing with a specific subarea of Machine Learning and, more generally, Artificial Intelligence. There are several approaches that are nowadays used for solving data mining and, more specifically, classification problems. The most common ones are (as for example described in [11]) decision tree learning, instance-based learning, inductive logic programming (such as using Prolog, e.g.) and reinforcement learning.

The task of a classification algorithm in the context of patient classification is to find a mathematical description that models underlying classification rules; this means that the diagnosis can be predicted by considering a set of other measured features (for example blood parameter values). Of

The work described in this paper was done within the Translational Research Project L282 "GP-Based Techniques for the Design of Virtual Sensors" sponsored by the Austrian Science Fund (FWF).

GECCO'06, July 8-12, 2006, Seattle, Washington, USA.

course, any data based classification algorithm can be applied to any given classification problem.

The application of data based machine learning techniques for learning classifiers is one of the major topics not only in computer science in general, but also especially in medical data mining. When it comes to automatically classifying patients into those which are possibly suffering from a certain disease and those which are healthy, one often has to face the problem that special tests (such as blood analysis, e.g.) produce high costs of time and money. This is why one has to seek for hidden relationships between the symptoms of a certain disease and other features which are much easier to measure.

In this paper we present a classification algorithm based on genetic programming (GP) [7] using a structure identification framework [18] originally designed for timeseries analysis, described in Section 2.1, in combination with an enhanced, hybrid selection scheme [1] (as explained in Section 2.2). This GP approach has been implemented as a part of the *HeuristicLab* [16], a framework for prototyping and analyzing optimization techniques for which both generic concepts of evolutionary algorithms and many functions to evaluate and analyze them are available.

The results obtained using this enhanced GP based identification approach are compared to those achieved by methods that are nowadays standard techniques in machine learning, namely linear regression modeling (Lin), (artificial) neural networks (NN) and k-nearest-neighbor (kNN) classification; detailed descriptions of these methods, theoretical background and actual variants and applications of these techniques can be found in [9], [4] and [15]. We also compare these results to those achieved using conventional GP techniques.

The comparison of the methods mentioned is done on the basis of three medical benchmark classification problems: The *Wisconsin* and the *Thyroid* data sets taken from the UCI Repository<sup>1</sup> as well as the *Melanoma* data set prepared by members of the Department of Dermatology of the Medical University Vienna. As we document in Section 3, the enhanced GP method presented here outperforms all other classification methods used in terms of classification accuracy on test data.

# 2. GP-BASED CLASSIFICATION IN MED-ICAL DIAGNOSTICS

# 2.1 The GP Based Structure Identification Approach

#### 2.1.1 General Remarks

Preliminary work for the approach presented in this paper was done for the project "Specification, Design, and Implementation of a Genetic Programming Approach for Identifying Nonlinear Models of Mechatronic Systems" as a part of a strategical project at the Johannes Kepler University Linz, Austria, focusing on system identification methods for mechatronic systems. It was successfully shown (see for instance [18]) that methods of GP are suitable for determining an appropriate mathematical representation of a physical, mechatronical system; especially the NO<sub>x</sub> and soot emissions of Diesel engines were investigated in this context yielding satisfying models (at least for  $NO_x$ ). The methods implemented for this project have been used for developing a GP-based statistical classification algorithm. This algorithm works on a set of training examples with known properties  $[X_1 \ldots X_n]$ ; one of these properties  $(X_t)$  has to represent the membership information with respect to the underlying taxonomy. In the context of medical applications, this target property gives the information about the respective patient's diagnosis (as "deseased" vs. "not deseased" or "malign" vs. "benign", e.g.). On the basis of the training examples, the algorithm tries to evolve (or, as one could also say, to "learn") a solution, i.e. a formula, that represents a function which maps a vector of object features into one of the given classes. In other words, each instance of the classification problem to be solved is interpreted as an instance of an optimization problem; a solution is found by a heuristic optimization algorithm.

The goal of the implemented GP classification process is to produce an algebraic expression from a database containing the measured results of the experiments to be analyzed. Thus, the GP algorithm works with solution candidates that are tree structure representations of symbolic expressions.

#### 2.1.2 Solution Candidate Representation Using Hybrid Tree Structures

The selection of the library functions is an important part of any GP modeling process [5] because this library should be able to represent a wide range of systems; Table 1 gives an overview of the function set as well as the terminal nodes used for the classification experiments documented in this paper. As the reader can see in Table 1, mathematical functions and terminal nodes are used as well as boolean operators for building complex arithmetic expressions. There are in fact no structural restrictions for the use of boolean blocks in formulae; of course, [Then/Else] and boolean expressions have to be connected to [IF] nodes, but there are no other restrictions regarding the use of boolean blocks within mathematical expressions. Thus, the concept of decision trees is included in this approach together with the standard structure identification concept that tries to evolve nonlinear mathematical expressions. An example showing the structure tree representation of a combined formula including arithmetic as well as logical functions is displayed in Figure 1.

#### 2.1.3 Evaluation of Classification Models

There are several possible functions that can serve as fitness functions within the GP process. For example, the ratio of misclassifications (using optimal thresholds) or the area under the corresponding ROC curves ([19], [3]) could be used. Another function frequently used for quantifying the quality of models is the  $R^2$  function that takes into account the sum of squared errors as well as the sum of squared target values; an alternative, the so-called *adjusted*  $R^2$  function, is also utilized in many applications.

Still, we have decided to use a variant of the squared errors function for estimating the quality of a classification model. There is one major difference of this modified mean squared errors function to the standard implementation of this function: The errors of predicted values that are lower than the lowest class value or greater than the greatest class value do not have a totally quadratic, but partially only linear contribution to the fitness value. To be a bit more

<sup>&</sup>lt;sup>1</sup>http://www.ics.uci.edu/~mlearn/

precise: Given N samples with original classifications  $o_i$  divided into n classes  $c_1, ..., c_n$  (with  $c_1$  being the lowest and  $c_n$  the greatest class value), the fitness value F of a classification model producing the estimated classification values  $e_i$  is evaluated as follows:

$$\forall_{i \in [1,N]} : (e_i < c_1) \Rightarrow f_i = (o_i - c_1)^2 + |c_1 - e_i|, \qquad (1)$$

$$(c_1 \le e_i \le c_n) \Rightarrow f_i = (e_i - o_i)^2, \qquad (2)$$

$$(e_i > c_n) \Rightarrow f_i = (o_i - c_n)^2 + |c_n - e_i| \qquad (3)$$

$$F = \frac{1}{N} \sum_{i=1}^{N} f_i \tag{4}$$

The reason for this is that values that are greater than the greatest class value or below the lowest value are anyway classified as belonging to the class having the greatest or the lowest class number, respectively; using a standard implementation of the squared error function would punish a formula producing such values more than necessary.

#### 2.1.4 Finding Appropriate Class Thresholds

Of course, a mathematical expression alone does not yet define a classification model; thresholds are used for dividing the output into multiple ranges, each corresponding to exactly one class. These regions are defined before starting the training algorithm in static range selection (SRS) [14], which brings along the difficulty of determining the appropriate range boundaries ahead of time. In the classification framework documented in this paper we have therefore used dynamic range selection (DRS) which attempts to overcome this problem by evolving the range thresholds along with the classification models. The thresholds are chosen so that the sum of ratios of misclassifications for all given classes is minimized (on the training data, of course).

#### 2.2 Introduction of an Enhanced Selection Scheme in the GP Process

In the context of our structure identification approach used for solving classification problems, the standard GP process (basically the procedure described in [7]) is extended by an enhanced selection scheme. Instead of using standard implementations of the genetic algorithm as underlying GP algorithm, a new generic evolutionary algorithm, the SASEGASA [1], is applied. This hybrid GA uses an enhanced selection model which is designed to directly control genetic drift within the population by advantageous selfadaptive selection pressure steering. Additionally, this new selection model enables to detect and combat premature convergence which is generally quite a critical issue in GAs. A very essential question about the general performance of GAs and especially GP is, whether or not good parents are able to produce children of comparable or even better fitness. For GAs, this property is not so easy to guarantee and for GP it is a matter of principle that many crossover and mutation results cause counterproductive solution candidates.

In order to overcome this drawback, the basic idea of the new selection model which we have called offspring selection (cf. Figure 2) is to consider not only the fitness of the parents in order to produce a child for the ongoing evolutionary process. Additionally, the fitness value of the evenly produced child is compared with the fitness values of its own parents. Basically the child is accepted as a candidate for the further evolutionary process if and only if the reproduction operator was able to produce a child that could outperform its better parent. Using the number of children that have to

Figure 2: Embedding the new offspring selection principle into a GA or GP.

be created in order to generate sufficiently many successful descendants, the so called selection pressure is calculated. This value can for example be used for further analysis of the execution of the GA or the GP process at hand, but also as a termination criterion by letting the algorithm automatically stop its execution as soon as the selection pressure exceeds a predefined upper limit.

For further details about the more specific parameters and functioning of offspring selection the interested reader is referred to [1] or [2].

This strategy guarantees that evolution is continued mainly with crossover results that were able to mix the properties of their parents in an advantageous way which is a very essential aspect for the preservation of essential genetic information stored in many individuals (which might not be the fittest in the sense of individual fitness). As elaborate test series have shown (see for example [18] [17] or [1]), the results obtained for various different optimization problems using the SASEGASA were significantly better than those produced by standard GA implementations.

# 3. EMPIRICAL TEST RESULTS

#### 3.1 Classification Methods Used

For comparing GP based classification with other machine learning methods, the following techniques for training classifiers were examined: Genetic programming (enhanced approach as described in Section 2), linear modeling, neural networks and the k-nearest-neighbor method. The benchmark problems analyzed are the data sets *Wisconsin*, *Melanoma* and *Thyroid*.

#### 3.1.1 GP based training of Classifiers

We have used the following parameter settings for our GP test series:

- Population size: 1000
- Mutation rate: 10%
- Selection scheme: SASEGASA selection incorporating offspring selection

- Selection operators: Roulette selection in combination with random selection
- Termination criteria:
  - Max. number of generations: 1000; not reached, all executions were terminated via the
  - Maximum selection pressure: 555 (as described in Section 2.2, details can be found in [1] and [2])
- Functions set: All functions as described in Section 2.1

In the case of the *Wisconsin* data set, the results retrieved using this enhanced GP (EGP) classification algorithm were compared to those obtained using standard GP techniques. In [14], for example, recent results for several classification benchmark problems are documented; the *Wisconsin* data set is also analyzed using standard GP as well as three other GP based classification variants (POPE-GP, DecMO-GP and DecMOP-GP).

#### 3.1.2 Linear modeling

Given a data collection including m input features storing the information about N samples, a linear model is defined by the vector of coefficients  $\theta_{1...m}$ . For calculating the vector of modeled values e using the given input values matrix  $u_{1...m}$ , these input values are multiplied with the corresponding coefficients and added:

$$e = u_{1\dots m} * \theta \tag{5}$$

The coefficients vector can be computed by simply applying matrix division. For conducting the test series documented here we have used the matrix division function provided by MATLAB:

#### theta = InputValues \ TargetValues;

If a constant additive factor is to be included into the model (i.e., the coefficients vector), this command has to be extended:

Theoretical background of this approach can be found in [9].

#### 3.1.3 Neural Networks

For training neural network (NN) models, three-layer feedforward neural networks with one output neuron were created using the Levenberg-Marquardt training method. Theoretical background and details can be found in [12] (Chapter 11, "Neural Networks"), [10], [8] or [6].

We have trained networks with 5 neurons in the hidden layer (referred to as "NN" in the test series documentation in Section 3.2) as well as networks with 10 hidden neurons (referred to as "NN2" in the test series documentation); the number of iterations of the training process was set to 300. In the context of analyzing the benchmark problems used here, higher numbers of nodes or iterations almost always lead to overfitting (i.e., a better fit on the training data, but worse test results).

The NN training framework used to collect the results reported in this paper is the NNSYSID20 package, a neural network toolbox for MATLAB implemented by Magnus Nørgaard at the Technical University of Denmark [13].

#### 3.1.4 kNN Classification

Unlike other data based modeling methods based on linear models, neural networks or GP, k-nearest-neighbor classification works without creating any explicit models. During the training phase, the data are simply collected; when it comes to classifying a new, unknown sample  $x_{new}$ , the sample-wise distance between  $x_{new}$  and all other training samples  $x_{train}$  is calculated and the classification is done on the basis of those k training samples  $(x_{NN})$  showing the smallest distances from  $x_{new}$ .

The distance between two samples is calculated as follows: First, all features are normalized by subtracting the respective mean values and dividing the remaining samples by the respective variables' variances. Given a data matrix x including m features storing the information about Nsamples, the normalized values  $x_{norm}$  are calculated as

$$\forall_{i \in [1,m]} \forall_{j \in [1,N]} : x_{norm}(i,j) = \frac{x(i,j) - \frac{1}{N} \sum_{k=1}^{N} x(i,k)}{var(x(i,1\dots N))}$$
(6)

where the variance var of a given variable x storing N values is calculated as

$$var(x) = \frac{1}{N-1} \sqrt{\sum_{i=1}^{N} (x_i - \bar{x})^2}$$
 (7)

with  $\bar{x}$  denoting the mean value of x.

Then, on the basis of the normalized data, the distance between two samples a and b, d(a, b), is calculated as the mean squared variable-wise distance:

$$d(a,b) = \frac{1}{n} \sum_{i=1}^{n} (a_{norm}(i) - b_{norm}(i))^2$$
(8)

where n again is the number of features stored for each sample.

In the context of classification, the numbers of instances (of the k nearest neighbors) are counted for each given class and the algorithm automatically predicts that class that is represented by the highest number of instances (included in  $x_{NN}$ ). In the test series documented in this paper we have applied weighting to kNN classification: The distance between  $x_{new}$  and  $x_{NN}$  is relevant for the classification statement, the weight of nearer samples is higher than that of samples that are "further" away from  $x_{new}$ .

There is a lot of literature that can be found for kNN classification; very good explanations and compact overviews of kNN classification (including several possible variants and applications) are for example given in [4] and [15].

#### 3.2 Results

All three data sets were investigated via 10-fold crossvalidation. This means that each original data set was divided into 10 disjoint sets of (approximately) equal size. Thus, 10 different pairs of training (90% of the data) and test data sets (10% of the data) can be formed and used for testing the classification algorithm. For the *Wisconsin* and the *Melanoma* data set we give the percentages of correct classifications for each partition and each modeling method tested. In the case of the *Thyroid* data set, the samples are not equally distributed to the three given classes; this is why we give the percentages of correct classifications for the *Thyroid* problem for each class separately. The Wisconsin as well as the *Thyroid* are parts of the UCI Machine Learning Repository<sup>1</sup> and also incorporated in the KEEL data set collection<sup>2</sup>; preprocessed versions of all data can be accessed in via the KEEL homepage<sup>3</sup>.

Table 2: Percentual correct classification rates for the classifiers produced for the 10-fold CV partitions of the *Wisconsin* data set.

<sup>2</sup>http://sci2s.ugr.es/keel/

<sup>&</sup>lt;sup>3</sup>Unfortunately, we had to realize that obviously this page has been relaunched and that the data are only partially accessible (at least on April 7, 2006). Therefore, the data are at the moment only available as raw data collections via the download section of the UCI Machine Learning repository: http://www.ics.uci.edu/~mlearn/databases.

#### 3.2.1 Wisconsin

The Wisconsin data set is a part of the UCI Machine Learning Repository; in short, it represents medical measurements which were recorded while investigating patients potentially suffering from breast cancer. The number of features recorded is 9, the file version we have used contains 683 recorded examples (by now, 699 examples are already available since the data base is updated regularily). A detailed description of the problem can be found on the KEEL homepage; the best results published using various classifiers (the best ones using problem specific methods achieving up to 98.7% accuracy on the training data and 98.5% on the test data) can be found there, too.

In Table 2 we give the percentages of correct classifications for each class evaluated on training data and on test data, respectively. The following training methods have been used: Linear modeling ("Lin"), neural networks ("NN": 5 hidden nodes, "NN2": 10 hidden nodes), kNN classification ("kNN", k = 3) and enhanced GP ("EGP").

An overview of the average percentages of correct classification for each method tested is given in Table 3. Additionally, we have compared the results to those achieved using other GP implementations documented in [14], namely "Standard GP", "POPE-GP", "DecMO-GP" and "DecMOP-GP".

#### 3.2.2 Melanoma

The *Melanoma* data set represents medical measurements which were recorded while investigating patients potentially suffering from skin cancer. It contains 1311 examples for which 30 features have been recorded; it has been provided to us by Prof. Michael Binder from the Departement of Dermatology at the Medical University Vienna, Austria.

In Table 4 we give the percentages of correct classifications for each class evaluated on training data and on test data, respectively. The following training methods have been used: Linear modeling ("Lin"), neural networks ("NN": 5 hidden nodes, "NN2": 10 hidden nodes), kNN classification ("kNN", k = 3) and enhanced GP ("EGP". An overview of the average percentages of correct classification for each method tested is given in Table 5.

#### 3.2.3 Thyroid

The *Thyroid* data set represents medical measurements which were recorded while investigating patients potentially suffering from hypotiroidism. A detailed description of the problem can be found on the KEEL homepage<sup>2</sup>. In short, the task is to determine whether a patient is hypothyroid or not. Three classes are formed: normal (not hypothyroid), hyperfunction and subnormal functioning; a good classifier has to be significantly better than 92% simply because 92 percent of the patients are not hyperthyroid. In total, the data set contains 7200 samples.

As already mentioned, the samples of the *Thyroid* data set are not equally distributed to the three given classes; in fact, 166 samples belong to class '1' ('subnormal functioning'), 368 samples are classified as '2' ('hyperfunction'), and the remaining 6666 samples belong to class '3' ('normal, not hypothyroid'). This is why we give the percentages of correct classifications for the *Thyroid* problem for each class separately. For the sake of readability we do not state the results for every partition, every class and every method; in the Tables 6 and 7 we give the percentages of correct classifi-

Table 4: Percentual correct classification rates for the classifiers produced for the 10-fold CV partitions of the *Melanoma* data set.

cations for each class in terms of average accuracy, standard deviation, minimum and maximum values for the methods tested on training data and on test data, respectively. The following training methods have been used: Linear mod-

eling, neural networks ("Variant 1": 5 hidden nodes, "Variant 2": 10 hidden nodes), kNN classification (k = 5) and enhanced GP.

#### 4. **DISCUSSION**

As documented in the Tables 2 until 7 it was able to show that for all three medical benchmark data sets the results achieved using the enhanced GP approach presented in this paper are - when evaluated on test data - better than those achieved applying linear regression, neural networks, neighborhood classification or standard genetic programming. Even though other methods achieve better fit and correct classification rates on the training data, using the GP based classification method described here yields the best results when it comes to classifying test samples, which is much more important than classifying training samples correctly.

Evaluated on the first data collection, the *Wisconsin* data set, neural networks are able to approximate the given data best showing a almost perfect fit (99.69% and 99.98% correct classifications, respectively) while enhanced GP is only able to produce classifiers with an average 98.09% classification accuracy. But when it comes to testing new, unknown data, the EGP method performs best; while the evaluation of the EGP method yields less than 3% test error, all other

methods perform significantly worse with average test errors ranging from 6.18% (standard GP) to 3.95% (linear modeling).

The evaluation of the classification method investigated using the *Melanoma* data set shows similar results:

While neural networks show a training error of less than 1.5%, the training error rate of the EGP method is more than twice as high (3.76%); only linear modeling performs worse (only 93.51% correct classification on training data). The test phase again shows that genetic programming methods are able to perform better than classical machine learning methods: The test error of the EGP method is 4.58% whereas neural networks produce 5.65% and 7.1% false classifications, respectively, and linear regression is also able to classify only 92.45% of the test samples correctly. Only kNN classification (5.65% test error) is able to perform almost as well, but still not quite as well as EGP.

The most challenging data set investigated is the *Thyroid* data set. As can be seen in Table 6, the linear modeling method is not able to produce satisfying classifiers. Neural networks are trained showing rather good fit on the training data: 91.47% (and 93.73%, respectively) of the training samples belonging to class 1 can be reconstructed correctly, 94.15% (96.68%) of class 2 and more than 99% of the training samples classified as "not hyperthyroid". EGP produces classifiers that are quite as good for class 1 and even a little bit better for classes 2 and 3 evaluated on the training data. As documented in Table 7, EGP obviously outperforms the other methods investigated significantly: kNN classification (with k = 5), for example, is on the average only able to correctly detect 32.52% of the test samples originally classified as '2', NN classifiers show lower correct classification rates then EGP. EGP yields best classifiers for the classes 1 and 2, only for class '3' kNN performs slightly better (99.42% correct classification opposed to 99.40% achieved by EGP).

# 5. CONCLUSION

In this paper we have presented an enhanced genetic programming method that was successfully used for investigating machine learning problems in the context of medical classification. The approach works with hybrid formula structures combining logical expressions (as used for example in decision trees) and classical mathematical functions; the enhanced selection scheme originally successfully applied for solving combinatorial optimization problems using genetic algorithms was also applied yielding high quality results.

As documented in the detailed test results summary, this genetic programming based classification approach outperforms classical machine learning algorithms frequently used for solving classification problems, namely linear regression, neural networks and neighborhood based classification.

The results achieved for the medical data collections are very satisfying and make the authors believe that an application in a real-world framework in the context of medical data analysis using the techniques presented here is strongly recommended .
